# Introduction to dplyr

When working with data you must:

- Figure out what you want to do.
- Precisely describe what you want in the form of a computer program.
- Execute the code.

The dplyr package makes each of these steps as fast and easy as possible by:

- Elucidating the most common data manipulation operations, so that your options are helpfully constrained when thinking about how to tackle a problem.
- Providing simple functions that correspond to the most common data manipulation verbs, so that you can easily translate your thoughts into code.
- Using efficient data storage backends, so that you spend as little time waiting for the computer as possible.

The goal of this document is to introduce you to the basic tools that dplyr provides, and show how you to apply them to data frames. Other vignettes provide more details on specific topics:

- databases: as well as in memory data frames, dplyr also connects to databases. It allows you
  to work with remote, out-of-memory data, using exactly the same tools, because dplyr will
  translate your R code into the appropriate SQL.
- benchmark-baseball: see how dplyr compares to other tools for data manipulation on a realistic use case.
- window-functions: a window function is a variation on an aggregation function, where an aggregate functions n inputs to produce 1 output, a window function uses n inputs to produce n outputs.

# Data: hflights

To explore the basic data manipulation verbs of dplyr, we'll start with the built in hflights data frame. This dataset contains all 227,496 flights that departed from Houston in 2011. The data comes from the US Bureau of Transporation Statistics, and is documented in ?hflights

```
library(hflights)
dim(hflights)
```

#> [1] 227496 21

### head(hflights)

```

```

dplyr can work with data frames as is, but if you're dealing with large data, it's worthwhile to convert them to a  $tb1\_df$ : this is a wrapper around a data frame that won't accidentally print a lot of data to the screen.

```
hflights_df <- tbl_df(hflights)
hflights_df</pre>
```

```

### **Basic verbs**

dplyr provides five basic data manipulation verbs that work on a single table: filter(), arrange(), select(), mutate() and summarise(). If you've used plyr before, many of these will be familiar.

# Filter rows with filter()

filter() allows you to select a subset of the rows of a data frame. The first argument is the name of the data frame, and the second and subsequent are filtering expressions evaluated in the context of that data frame:

For example, we can select all flights on January 1st with:

```
filter(hflights_df, Month == 1, DayofMonth == 1)
```

```
#> Source: local data frame [552 x 21]

     CancellationCode (chr), Diverted (int)
#>
```

This is equivalent to the more verbose:

```
hflights[hflights$Month == 1 & hflights$DayofMonth == 1, ]
```

filter() works similarly to subset() except that you can give it any number of filtering conditions which are joined together with & (not & which is easy to do accidentally!). You can use other boolean operators explicitly:

```
filter(hflights_df, Month == 1 | Month == 2)
```

# **Arrange rows with** arrange()

arrange() works similarly to filter() except that instead of filtering or selecting rows, it reorders them. It takes a data frame, and a set of column names (or more complicated expressions) to order by. If you provide more than one column name, each additional column will be used to break ties in the values of preceding columns:

```
arrange(hflights_df, DayofMonth, Month, Year)
```

```

#>
     CancellationCode (chr), Diverted (int)
#>
```

dplyr::arrange() works the same way as plyr::arrange(). It's a straighforward wrapper around order() that requires less typing. The previous code is equivalent to:

```
hflights[order(hflights$DayofMonth, hflights$Month, hflights$Year), ] hflights[order(desc(hflights$ArrDelay)), ]
```

# Select columns with select()

Often you work with large datasets with many columns where only a few are actually of interest to you. select() allows you to rapidly zoom in on a useful subset using operations that usually only work on numeric variable positions:

```
# Select columns by name
select(hflights_df, Year, Month, DayOfWeek)
```

```
#> Source: local data frame [227,496 x 3]
#>
#>

     (chr), Dest (chr), Distance (int), TaxiIn (int), TaxiOut (int),
#>
#>
     Cancelled (int), CancellationCode (chr), Diverted (int)
```

This function works similarly to the select argument to the base::subset(). It's its own function in dplyr, because the dplyr philosophy is to have small functions that each do one thing well.

## **Add new columns with mutate()**

As well as selecting from the set of existing columns, it's often useful to add new columns that are functions of existing columns. This is the job of mutate():

```
mutate(hflights_df,
  gain = ArrDelay - DepDelay,
  speed = Distance / AirTime * 60)
```

```

#>
```

dplyr::mutate() works the same way as plyr::mutate() and similarly to
base::transform(). The key difference between mutate() and transform() is that mutate
allows you to refer to columns that you just created:

```
mutate(hflights_df,
  gain = ArrDelay - DepDelay,
  gain_per_hour = gain / (AirTime / 60)
)
```

```

#>
     CancellationCode (chr), Diverted (int), gain (int), gain_per_hour (dbl)
#>
```

```
transform(hflights,
  gain = ArrDelay - DepDelay,
  gain_per_hour = gain / (AirTime / 60)
)
#> Error: object 'gain' not found
```

# Summarise values with summarise()

The last verb is summarise(), which collapses a data frame to a single row. It's not very useful yet:

```
summarise(hflights_df,
  delay = mean(DepDelay, na.rm = TRUE))
```

```
#> Source: local data frame [1 x 1]
#>
#> delay
#> 1 9.445
```

This is exactly equivalent to plyr::summarise().

## **Commonalities**

You may have noticed that all these functions are very similar:

- The first argument is a data frame.
- The subsequent arguments describe what to do with it, and you can refer to columns in the data frame directly without using \$\].
- The result is a new data frame

Together these properties make it easy to chain together multiple simple steps to achieve a complex result.

These five functions provide the basis of a language of data manipulation. At the most basic level, you can only alter a tidy data frame in five useful ways: you can reorder the rows (arrange()), pick observations and variables of interest (filter() and select()), add new variables that are functions of existing variables (mutate()) or collapse many values to a summary (summarise()). The remainder of the language comes from applying the five functions to different types of data, like to grouped data, as described next.

# **Grouped operations**

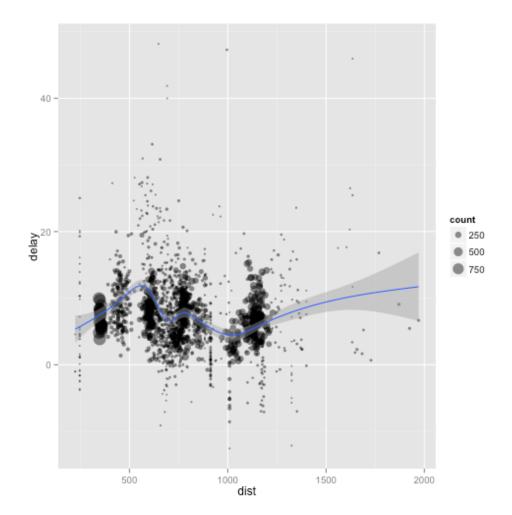

These verbs are useful, but they become really powerful when you combine them with the idea of "group by", repeating the operation individually on groups of observations within the dataset. In dplyr, you use the group\_by() function to describe how to break a dataset down into groups of rows. You can then use the resulting object in the exactly the same functions as above; they'll automatically work "by group" when the input is a grouped.

Of the five verbs, select() is unaffected by grouping, and grouped arrange() orders first by grouping variables. Group-wise mutate() and filter() are most useful in conjunction with window functions, and are described in detail in the corresponding vignette(). summarise() is easy to understand and very useful, and is described in more detail below.

In the following example, we split the complete dataset into individual planes and then summarise each plane by counting the number of flights (count = n()) and computing the average distance (dist = mean(Distance, na.rm = TRUE)) and delay(delay = mean(ArrDelay, na.rm = TRUE)). We then use ggplot2 to display the output.

```
planes <- group_by(hflights_df, TailNum)
delay <- summarise(planes,
    count = n(),
    dist = mean(Distance, na.rm = TRUE),
    delay = mean(ArrDelay, na.rm = TRUE))
delay <- filter(delay, count > 20, dist < 2000)

# Interestingly, the average delay is only slightly related to the
# average distance flown a plane.
ggplot(delay, aes(dist, delay)) +
    geom_point(aes(size = count), alpha = 1/2) +
    geom_smooth() +
    scale_size_area()</pre>
```

You use summarise() with **aggregate functions**, which take a vector of values, and return a single number. There are many useful functions in base R like min(), max(), mean(), sum(), sd(), median(), and IQR(). dplyr provides a handful of others:

- n(): number of observations in the current group
- n\_distinct(x): count the number of unique values in x.
- first(x), [last(x)] and [last(x)] and [last(x)] and [last(x)] and [last(x)] and [last(x)] but give you more control of the result if the value isn't present.

For example, we could use these to find the number of planes and the number of flights that go to each possible destination:

```
destinations <- group_by(hflights_df, Dest)
summarise(destinations,
  planes = n_distinct(TailNum),
  flights = n()
)</pre>
```

```
#> Source: local data frame [116 x 3]
#>
#>
      Dest planes flights
#> 1
               716
                      2812
       ABQ
#> 2
               215
                       724
       AEX
#> 3
       AGS
                 1
                          1
#> 4
       AMA
               158
                      1297
#> ..
               . . .
```

You can also use any function that you write yourself. For performance, dplyr provides optimised C++ versions of many of these functions. If you want to provide your own C++ function, see the hybrid-evaluation vignette for more details.

When you group by multiple variables, each summary peels off one level of the grouping. That makes it easy to progressively roll-up a dataset:

```
daily <- group_by(hflights_df, Year, Month, DayofMonth)
(per_day <- summarise(daily, flights = n()))</pre>
```

```
#> Source: local data frame [365 x 4]
#> Groups: Year, Month
#>
#>
      Year Month DayofMonth flights
#> 1
      2011
                1
                            1
                                   552
#> 2
      2011
                1
                            2
                                   678
#> 3 2011
                1
                            3
                                   702
#> 4 2011
                1
                            4
                                   583
#> ..
                                   . . .
                          . . .
```

```
(per_month <- summarise(per_day, flights = sum(flights)))</pre>
```

```
#> Source: local data frame [12 x 3]
#> Groups: Year
#>
#>
      Year Month flights
#> 1
     2011
               1
                   18910
#> 2
     2011
               2
                   17128
#> 3 2011
               3
                   19470
#> 4 2011
               4
                   18593
#> .. ...
```

```
(per_year <- summarise(per_month, flights = sum(flights)))</pre>
```

```
#> Source: local data frame [1 x 2]
#>
#> Year flights
#> 1 2011 227496
```

However you need to be careful when progressively rolling up summaries like this: it's ok for sums and counts, but you need to think about weighting for means and variances, and it's not possible to do exactly for medians.

# Chaining

The dplyr API is functional in the sense that function calls don't have side-effects, and you must always save their results. This doesn't lead to particularly elegant code if you want to do many operations at once. You either have to do it step-by-step:

```
a1 <- group_by(hflights, Year, Month, DayofMonth)
a2 <- select(a1, Year:DayofMonth, ArrDelay, DepDelay)
a3 <- summarise(a2,
   arr = mean(ArrDelay, na.rm = TRUE),
   dep = mean(DepDelay, na.rm = TRUE))
a4 <- filter(a3, arr > 30 | dep > 30)
```

Or if you don't want to save the intermediate results, you need to wrap the function calls inside each other:

```
filter(
   summarise(
     select(
        group_by(hflights, Year, Month, DayofMonth),
        Year:DayofMonth, ArrDelay, DepDelay
   ),
   arr = mean(ArrDelay, na.rm = TRUE),
   dep = mean(DepDelay, na.rm = TRUE)
   ),
   arr > 30 | dep > 30
)
```

```
#> Source: local data frame [14 x 5]
#> Groups: Year, Month
#>
     Year Month DayofMonth
#>
                             arr
                                   dep
#> 1 2011
                         4 44.08 47.17
#> 2 2011
               3
                          3 35.13 38.20
#> 3 2011
                         14 46.64 36.14
#> 4 2011
              4
                          4 38.72 27.95
#> .. ...
                              . . .
```

This is difficult to read because the order of the operations is from inside to out, and the arguments are a long way away from the function. To get around this problem, dplyr provides the  $\frac{\%}{\%}$  operator.  $\frac{(x \%)^{\%}}{\%}$  turns into  $\frac{(x, y)}{\%}$  so you can use it to rewrite multiple operations so you can read from left-to-right, top-to-bottom:

```
hflights %>%
  group_by(Year, Month, DayofMonth) %>%
  select(Year:DayofMonth, ArrDelay, DepDelay) %>%
  summarise(
    arr = mean(ArrDelay, na.rm = TRUE),
    dep = mean(DepDelay, na.rm = TRUE)
) %>%
  filter(arr > 30 | dep > 30)
```

## Other data sources

As well as data frames, dplyr works with data stored in other ways, like data tables, databases and multidimensional arrays.

### Data table

8/1/14

dplyr also provides <u>data table</u> methods for all verbs. If you're using data.tables already this lets you use dplyr syntax for data manipulation, and data.table for everything else.

For multiple operations, data.table can be faster because you usually use it with multiple verbs at the same time. For example, with data table you can do a mutate and a select in a single step, and it's smart enough to know that there's no point in computing the new variable for the rows you're about to throw away.

The advantages of using dplyr with data tables are:

- For common data manipulation tasks, it insulates you from reference semantics of data.tables, and protects you from accidentally modifying your data.
- Instead of one complex method built on the subscripting operator ([), it provides many simple methods.

### **Databases**

dplyr also allows you to use the same verbs with a remote database. It takes care of generating the SQL for you so that you can avoid the cognitive challenge of constantly swiching between languages. See the databases vignette for more details.

Compared to DBI and the database connection algorithms:

- it hides, as much as possible, the fact that you're working with a remote database
- you don't need to know any sql (although it helps!)
- it shims over the many differences between the different DBI implementations

# Multidimensional arrays / cubes

tbl\_cube() provides an experimental interface to multidimensional arrays or data cubes. If you're using this form of data in R, please get in touch so I can better understand your needs.

# **Comparisons**

Compared to all existing options, dplyr:

- abstracts away how your data is stored, so that you can work with data frames, data tables
  and remote databases using the same functions. This lets you think about what you want to
  achieve, not the logistics of data storage.
- it provides a thoughtful default <a href="mailto:print()">print()</a> method so you don't accidentally print pages of data to the screen (this was inspired by data tables output)

#### Compared to base functions:

- dplyr is much more consistent; functions have the same interface so that once you've mastered one, you can easily pick the others
- base functions tend to be based around vectors; dplyr is centered around data frames

#### Compared to plyr:

- dplyr is much much faster
- · it provides a better thought out set of joins
- it only provides tools for working with data frames (e.g. most of dplyr is equivalent to ddply()
   + various functions, do() is equivalent to dlply()

#### Compared to virtual data frame approaches:

• it doesn't pretend that you have a data frame: if you want to run Im etc, you'll still need to manually pull down the data

• it doesn't provide methods for R summary functions (e.g. mean(), or sum())
